

Project 2 / Risk Management

2024-04-16

In this report, we implement part of the risk management framework for estimating the risk of a book of European call options on the S&P500. We take into account two risk drivers: the underlying and implied volatility.

For near-the-money calls and for efficiency, we protect by vectorizing, clearing and organizing our data on the S&P500, the VIX index, term structure of interest rates, and traded options.

```

Pricing of a portfolio of options

We begin by assuming the book of European call options: 1x strike K = 1000 maturity 20 days, 1x strike K = 1000 maturity 20 days, 1x strike K = 1750 maturity 40 days and 1x strike K = 1000 maturity 40 days.

To price our options, we apply Black-Scholes with the latest price of the underlying, the latest implied volatility (i.e. VIX for all options) and we linearly interpolate the term structure of interest rates to find the corresponding rate.

We assume 360 days/year for the term structure and 250 days/year for the time to maturity of options.

```
# price options using Black-Scholes
variables$options_prices <- f_pricing(
  S = dplyr::last(variables$index_prices$SP500),
  sd = dplyr::last(variables$index_prices$VIX),
  K = variables$options_strike_price,
  t = variables$options_maturity,
  rf = variables$rf_rate,
  rf_t = variables$rf_maturity)

# Do not overwrite original variable because slice()-l loses data.
```

```
# Do not overwrite original variable because slice()-l loses data.
```

```
# Compute log rets & store
variables$index_prices <- variables$index_prices %>%
  dplyr::mutate(
    .cols = c(SP500, VIX),
    .fn = ~log(1 + dplyr::lag(log(.),
      .names = ~"col_log_return"
    )) %>%
    dplyr::slice(-1)

# Fit normal distribution to rets
y <- dplyr::last(variables$index_prices$SP500_log_return)
sig_hat <- f_fitGaussian(y)

# Simulate 5 days ahead prices
n_sim <- 10000
sis_prices <- f_forecastPrices(
  n_sim = n_sim,
  mu = sig_hat$mean,
  sd = sig_hat$sd,
  S = dplyr::last(variables$index_prices$SP500))

# Initialize
sis_optionPrices <- matrix(ncol = length(sis_prices),
  row = length(variables$options_strike_price))

# Find options price for simulated scenarios
for (i in seq_along(sis_prices)) {
  sim_optionPrices[i, ] <- f_pricing(
    S = sis_prices[i, ],
    sd = dplyr::last(variables$index_prices$VIX),
    K = variables$options_strike_price,
    t = variables$options_maturity,
    rf = variables$rf_rate,
    rf_t = variables$rf_maturity)
}

# Subtract option price at t_0 from simulated scenario prices at t_1
profitLoss <- sweep(sis_optionPrices, MARGIN = 1, variables$options_prices, "-")

# Sum the P&L of all options for each scenario
book_pnl <- colSums(profitLoss)

# Determine distribution of P&L book of options
theta_hat2 <- f_fitGaussian(book_pnl)
theta_hat2
```

```
## $mean
## [1] -40.6824
##
## $sd
## [1] 249.7386
```

We now plot the P&L distribution of our book of options.

```
f_ES <- function(p, mu = 0, sd = 1)(mu + sd * dnorm(qnorm(p)) / (1 - p)) #Quick ES helper function

# VaR95 and ES95
p <- 0.95
VaR95 <- quantile(book_pnl, p)[1]
ES95 <- -VaR95
VaR95
```

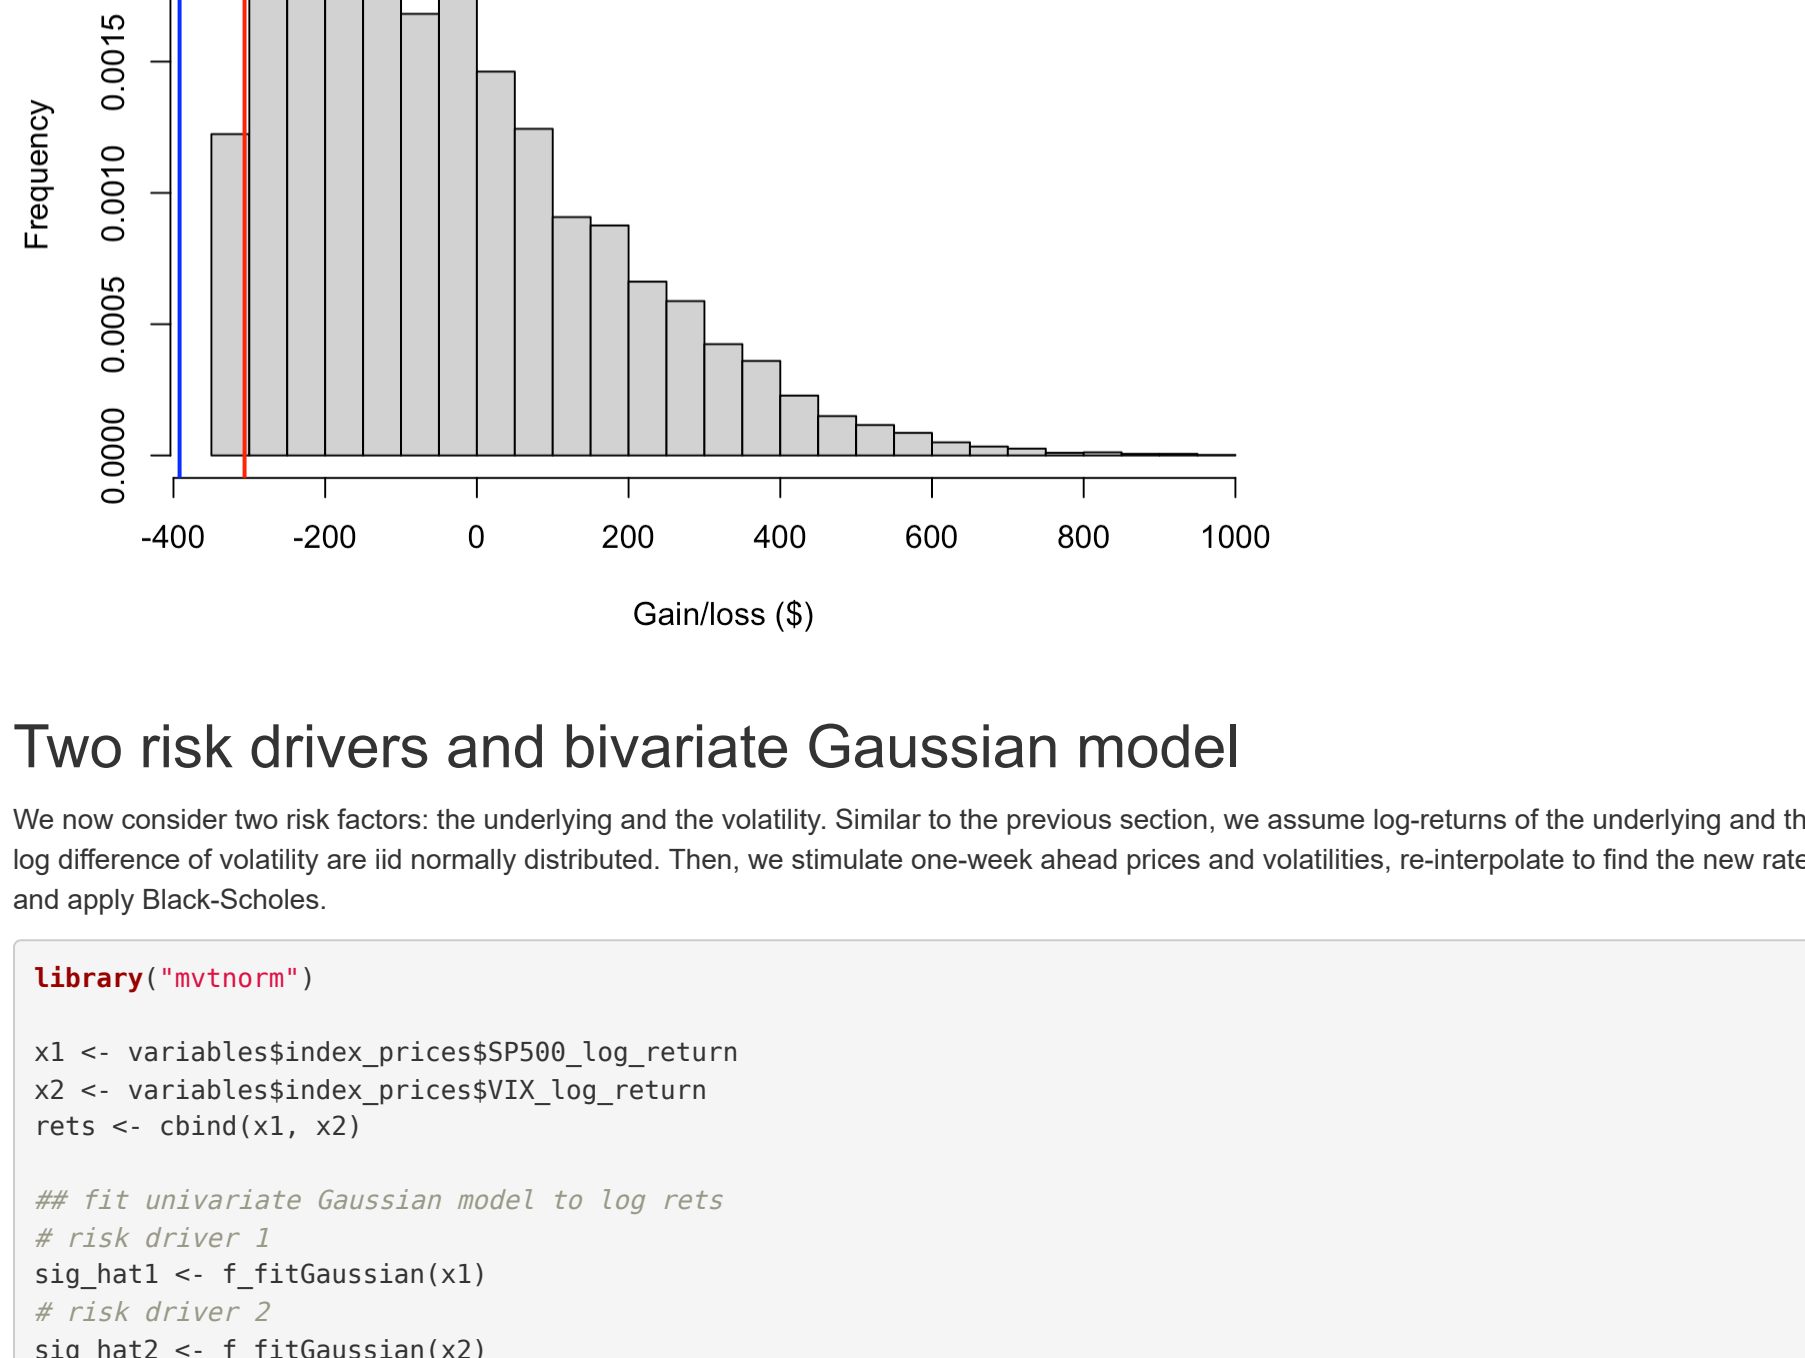

```
## [1] 306.2875

ES95 <- -f_ES(0.95, theta_hat2$mean, theta_hat2$sd)
ES95
```

```
## [1] -391.948

# Plot P&L
hist(book_pnl,
  main = "P&L distribution (One risk driver)",
  xlab = "Gain/Loss ($)",
  ylab = "Frequency",
  breaks = 25,
  border = "black",
  freq = FALSE)

abline(v = VaR95, col = "red", lwd = 2)
abline(v = ES95, col = "blue", lwd = 2)
legend("topright", legend = c("VaR 95", "ES 95"), col = c("red", "blue"), lwd = 2)
```

Two risk drivers and bivariate Gaussian model

We now consider two risk drivers: the underlying and the volatility. Similar to the previous section, we assume log-returns of the underlying and the log difference of volatility are not normally distributed. Then, we simulate one-week ahead prices and volatilities, re-interpolate to find the new rate and apply Black-Scholes.

```
library("rstanarm")

x1 <- variables$index_prices$SP500_log_return
x2 <- variables$index_prices$VIX_log_return
rets <- cbind(x1, x2)

# Fit univariate Gaussian model to log rets
# risk driver
sig_hat1 <- f_fitGaussian(x1)
# risk driver
sig_hat2 <- f_fitGaussian(x2)

# Simulate 10000 log rets with multivariate Gaussian model
n_sim <- 10000
mu <- c(sig_hat1$mean, sig_hat2$mean)
sigma <- cov(rets)
S <- dplyr::last(variables$index_prices$SP500)
VIX <- dplyr::last(variables$index_prices$VIX)

# Get prices from simulated log rets using the bivariate model
sample_prices <- matrix(ncol = n_sim, ncol = 2)
for (i in 1:n_sim) {
  sample_rets <- rmvnorm(1, mean = mu, sigma = sigma)
  sample_prices[i, ] <- last(S * exp(cumsum(sample_rets[, 1])))
  sample_prices[i, 2] <- last(VIX * exp(cumsum(sample_rets[, 2])))
}

# Value options using simulated values. Take interpolated rates for the term structure
sis_optionPrices2 <- matrix(ncol = n_sim,
  row = length(variables$options_strike_price))

for (i in seq_along(sis_prices)) {
  sim_optionPrices[i, ] <- f_pricing(
    S = sample_prices[i, 1],
    sd = sample_prices[i, 2],
    K = variables$options_strike_price,
    t = variables$options_maturity,
    rf = variables$rf_rate,
    rf_t = variables$rf_maturity)
}

# Find P&L by subtracting initial option price at t_0 from each scenario price at t_1
profitLoss2 <- sweep(sis_optionPrices2, MARGIN = 1, variables$options_prices, "-")
book_pnl2 <- colSums(profitLoss2)

hist(book_pnl2,
  main = "P&L distribution (Two risk drivers)",
  xlab = "Gain/Loss ($)",
  ylab = "Frequency",
  breaks = 20,
  border = "black")
```

Two risk drivers and copula-marginal model

Considering multiple risk factors makes an improvement from the last method, although it still suffers from a major drawback when the distribution of the underlying returns or the log difference of the VIX are not actually normally distributed. In other words, the simulated observations through the multivariate normal distribution depend on the way the marginals are not necessarily normal. We thus turn towards Copulas to solve this.

In order to strictly isolate any dependence structure between our risk factors, we turn to Copulas.

We now assume the returns of the underlying to follow a Student-t distribution with $\nu = 10$ degrees of freedom and the log-difference of the VIX to follow a Student-t distribution with $\nu = 5$ degrees of freedom. We will use the normal copula to merge the marginals, recompute the P&L and the risk figures.

```
library("copula")
library("MASS")
library("fGarch")

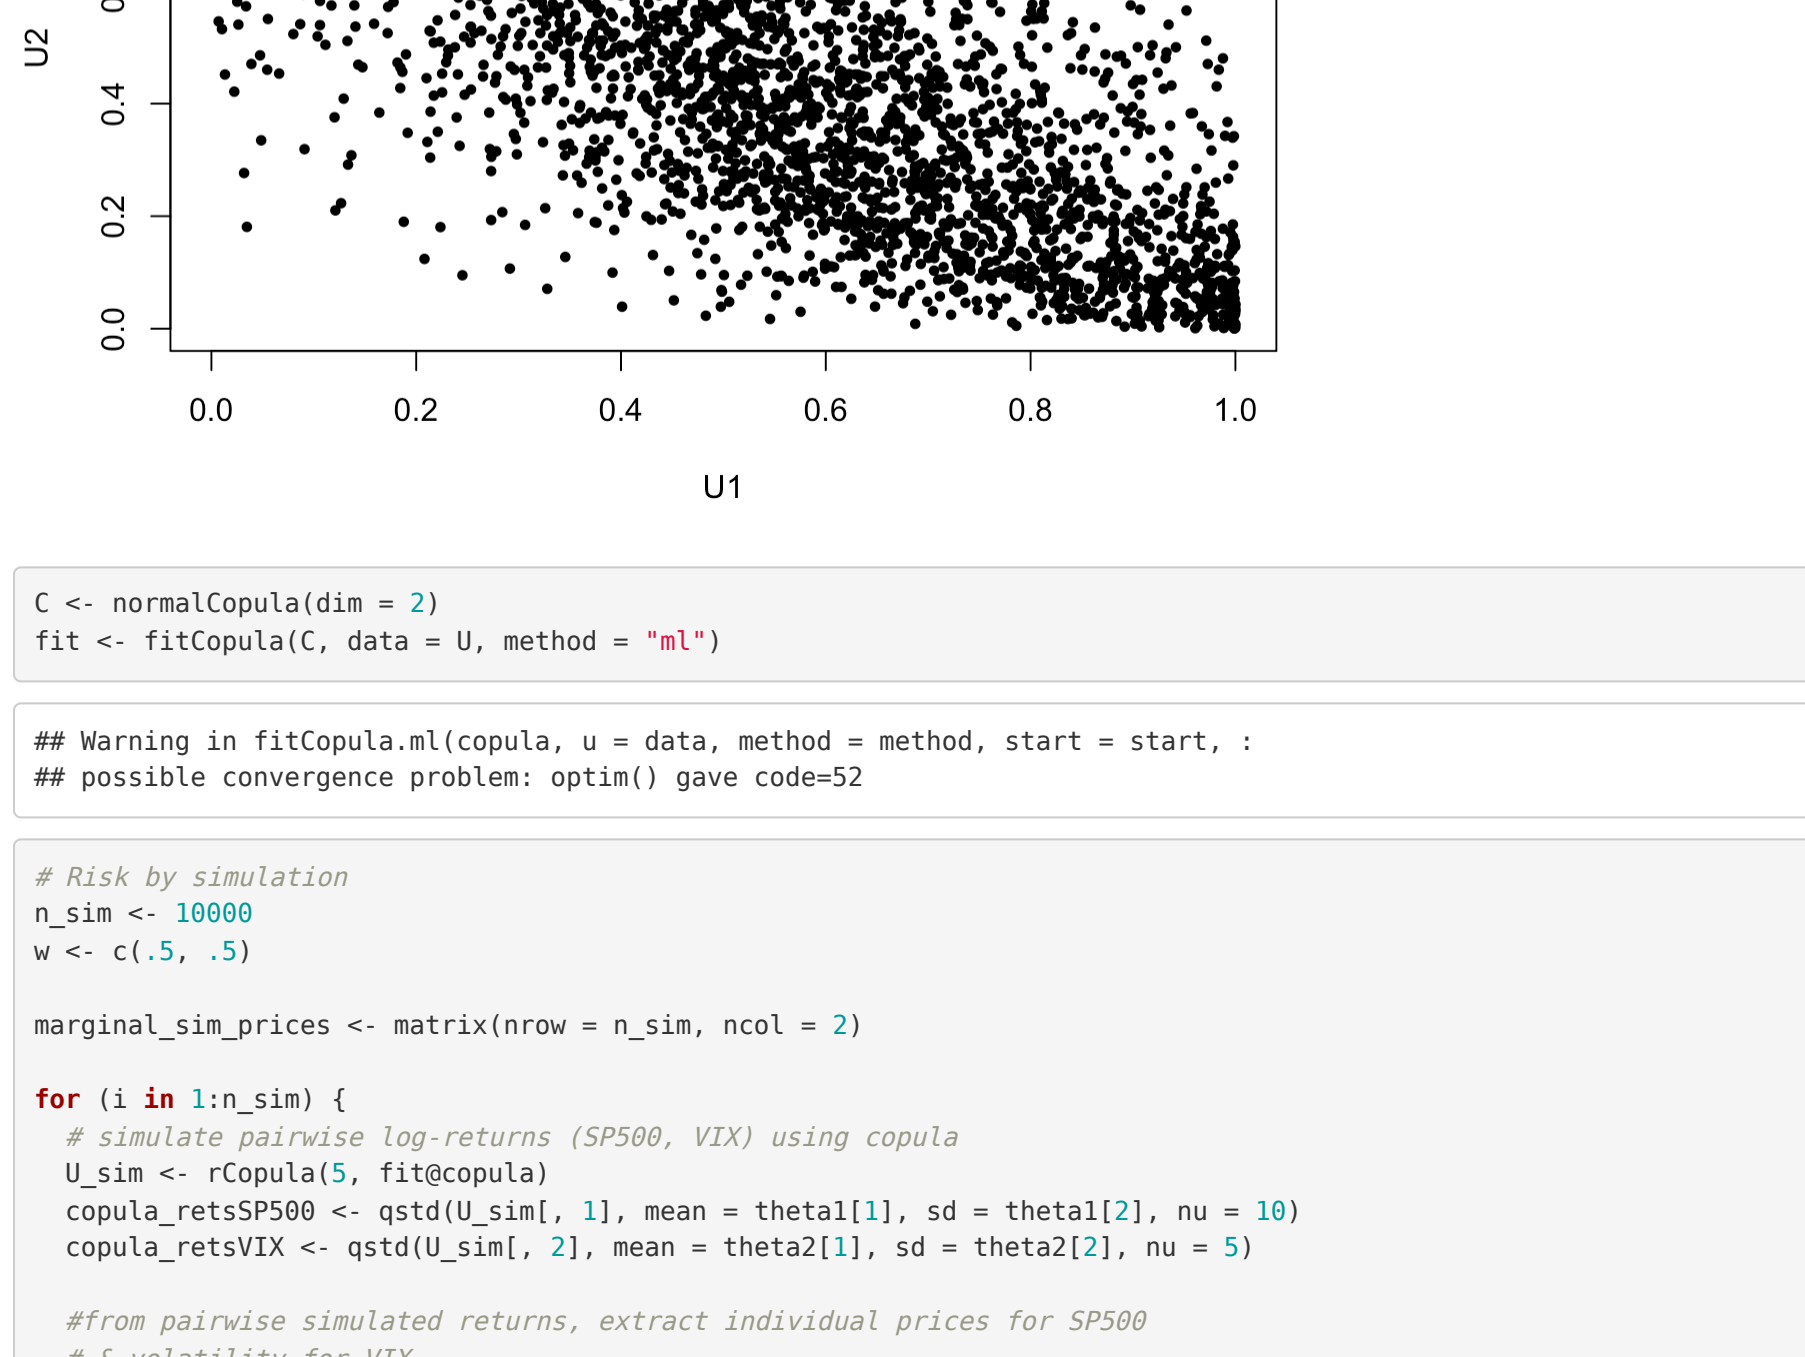

x1 <- variables$index_prices$SP500_log_return
x2 <- variables$index_prices$VIX_log_return
set.seed(123)

# Fit Student-t marginals to log rets of SP500 & VIX by MLE
fit1 <- suppressWarnings(
  fitdist(x1, dnorm = dstd, nu = 10, start = list(mean = 0, sd = 1)))
fit2 <- suppressWarnings(
  fitdist(x2, dnorm = dstd, nu = 5, start = list(mean = 0, sd = 1)))

theta1 <- fit1$estimate
theta2 <- fit2$estimate

# Fit Gaussian copula
U1 <- pstd(x1, mean = theta1[, 1], sd = theta1[, 2], nu = 10) #10 degrees of freedom
U2 <- pstd(x2, mean = theta2[, 1], sd = theta2[, 2], nu = 5)
U <- cbind(U1, U2)

plot(U, pch = 20, cex = 0.5, main = "Gaussian Copula")
```

```
C <- normalCopula(d = 2)
fit <- fitCopula(C, data = U, method = "ml")

## Warning in fitCopula.ml(copula, u = data, method = method, start = start.):
## possible convergence problem: optml gave code=2
```

```
# Risk by simulation
n_sim <- 10000
u <- c(1.5, .5)

marginal_sis_prices <- matrix(nrow = n_sim, ncol = 2)

for (i in 1:n_sim) {
  # Simulate pairwise log-returns (SP500, VIX) using copula
  U <- cbind(U1, U2)
  copula_retsSP500 <- qstd(U[, 1], mean = theta1[, 1], sd = theta1[, 2], nu = 10)
  copula_retsVIX <- qstd(U[, 2], mean = theta2[, 1], sd = theta2[, 2], nu = 5)

  # Pairwise simulated returns, extract individual prices for SP500
  # & volatility for VIX
  marginal_sis_prices[i, ] <- last(S * exp(cumsum(copula_retsSP500))) #for SP500
  copula_sis_prices[i, ] <- last(VIX * exp(cumsum(copula_retsVIX))) #for VIX
}

# Value book of options using Copula-simulated prices & VIX
# Then interpolate rates for the term structure
sis_optionPrices3 <- matrix(ncol = length(sis_prices),
  row = length(variables$options_strike_price))

for (i in 1:n_sim) {
  sim_optionPrices[i, ] <- f_pricing(
    S = marginal_sis_prices[i, 1],

abline(v = ES95_copula, col = "blue", lwd = 2)
legend("topright", legend = c("VaR 95", "ES 95"), col = c("red", "blue"), lwd = 2)
```

Volatility surface

The Black-Scholes model assumes volatility to be constant and returns to be log normally distributed, which is not particularly what the market exhibits. To compensate for this, we now make use of the volatility surface.

For the code below, we will work with the parametric surface $\sigma(m, \tau) = \sigma_1 + \sigma_2(m - 1)^2 + \sigma_3(\tau - 1)^3 + \sigma_4$, where $m = \frac{K}{S}$ is the moneyness and τ is the time to maturity of the option in years.

We now fit a volatility surface to the implied volatilities observed on the market (traded call and put options). Then, we minimize the absolute distance between the model-implied volatilities and the model-implied volatilities.

```
ctrl_opts_chunkSize(warning = FALSE, message = FALSE)

# calculate moneyness for calls
calls_moneyness <- variables$calls %>%
  dplyr::mutate(strike = K, maturity = tau, market_vol = IV) %>%
  dplyr::mutate(moneyness = strike / dplyr::last(variables$index_prices$SP500))

# calculate moneyness for puts
puts_moneyness <- variables$puts %>%
  dplyr::mutate(strike = K, maturity = tau, market_vol = IV) %>%
  dplyr::mutate(moneyness = strike / dplyr::last(variables$index_prices$SP500))

# concat both moneyness (for puts and calls)
implied_vols <- dplyr::bind_rows(
  calls_moneyness %>% dplyr::select(strike, maturity, moneyness, market_vol),
  puts_moneyness %>% dplyr::select(strike, maturity, moneyness, market_vol)
)

# Fit volatility surface model against puts and calls
# Find optimal parameters
fitted_surface_params <- f_fitVolSurface(m = implied_vols$moneyness,
  tau = implied_vols$maturity,
  market_vols = implied_vols$market_vol)

# Compute volatilities with parameter estimates
implied_vols$justed_vol <- f_VolatilitySurface(m = implied_vols$moneyness,
  tau = implied_vols$maturity,
  params = as.numeric(fitted_surface_params))

# Plot the volatility surface (see viewer tab)
interp_data <- akima::interp(
  m = implied_vols$moneyness,
  tau = implied_vols$maturity,
  z = implied_vols$justed_vol,
  duplicate = "mean",
  yo = seq(min(implied_vols$moneyness), max(implied_vols$moneyness), length = 100),
  x = seq(min(implied_vols$maturity), max(implied_vols$maturity), length = 100))
